Abstract

We propose a new method to extract a CP angle γ from semi-inclusive two-body nonleptonic decays, $b \rightarrow D^0(\bar{D}^0)s$ and $b \rightarrow D_{CP}s$. This method is free from the unknown long distance strong interaction effects and gives theoretically cleaner signal than the similar method using exclusive nonleptonic decays, $B \rightarrow DK$. We can determine γ with $4\text{-}\sigma$ accuracy for $40^\circ \lesssim \gamma \lesssim 160^\circ$.

In the standard model (SM), the source of CP asymmetry is one complex phase in the Cabibbo-Kobayashi-Maskawa (CKM) matrix element [1]. Until now, only one experimental evidence of CP violation is found in $K_L \rightarrow \pi\pi$ decay and it comes dominantly from $K^0 - \bar{K}^0$ mixing. Hence it should be important to probe the CP violation in the B systems in the future experiment in order to test the SM scenario of CP violation. One of the important objects to investigate CP violation is the unitary triangle which includes three angles α, β and γ . The angles β and γ are related to V_{td} and V_{ub} respectively and the angle α is obtained using the unitary relation $\alpha + \beta + \gamma = \pi$. The recent numerical constraints of the three angles are given [2] :

$$\begin{aligned} -1.0 &\leq \sin 2\alpha \leq 1.0, \\ 0.30 &\leq \sin 2\beta \leq 0.88, \\ 0.27 &\leq \sin^2 \gamma \leq 1.0. \end{aligned} \tag{1}$$

There are many suggestions to determine independently the angles of the unitary triangle. For example, the angle α can be determined by $B \rightarrow \pi\pi$ modes if their gluonic penguin pollutions can be removed using the isospin relation [3]. The $B \rightarrow J/\psi K_S$ decay is gold-plated mode to determine the angle β because the CKM angles from decay processes are almost canceled in the rate asymmetry and it can be unambiguously determined by $B^0 - \bar{B}^0$ mixing which is related to the angle β . The angle γ may be obtained by $B \rightarrow DK$ modes [4,5]. But it is noted in [6] that this method has the experimental difficulties because the final $\bar{D}^0$ meson should be identified using $\bar{D}^0 \rightarrow K^+\pi^-$, but it is difficult to distinguish it from doubly Cabibbo suppressed $D^0 \rightarrow K^+\pi^-$ following color and CKM allowed $B^- \rightarrow D^0 K^-$. There are some variant methods to overcome these difficulties [6–9]. In Ref. [6], the interference between $B^- \rightarrow D^0[\rightarrow \pi^- K^+]K^-$ decay and $B^- \rightarrow \bar{D}^0[\rightarrow \pi^- K^+]K^-$ decay is used. The extraction method of the angle γ using the color-allowed decays only is proposed in Ref. [7]. In Ref. [8,9], authors proposed the extraction method of γ using the isospin relation and neglecting the annihilation diagrams.

Other methods to constrain the angle γ from $B \rightarrow K\pi$ modes has been also proposed in Ref. [10]. However the long distance strong interaction effects might destroy the validity of this method [11]. These uncertainties and electro-weak penguin pollutions can be removed by using the $B \rightarrow KK$ modes and $SU(3)$ flavor symmetry [12]. Such rescattering effects may be potentially important in any exclusive decays of B meson decays and it is important to remove hadronic uncertainties coming from the rescattering effects.

It is noted by several authors that inclusive and semi-inclusive decays of B meson could show large CP violation [14–16]. In Ref. [14], the authors estimate the rate asymmetry using the absorptive part of the decay amplitude. Gerard and Hou [14] noted that CPT theorem is violated if one does not include all diagrams of the same order. The CP violation in the semi-inclusive charmless, single charm and double charm transition is considered in Ref. [15]. Moreover as the large cancellation between the semi-inclusive decay rates, the CP violation effects in the totally inclusive decays are expected to be tiny. However one can expect the large CP violation in the each of the semi-inclusive decays. Authors in Ref. [16] investigate the CP violation in the quasi-inclusive decays of the type $B \rightarrow K^{(*)}X$ that the strange quark is only included in $K^{(*)}$ meson. The interference between the tree level process $b \rightarrow u\bar{u}s$ and the one loop process $b \rightarrow sg^* \rightarrow sq\bar{q}$ gives the direct CP violation.

In the Ref. [13], authors proposed a systematic method of experimental search for two-body hadronic decays of the b -quark of the type $b \rightarrow quark(q) + meson(M)$. They have the well-defined experimental signature because the spectrum of the meson energy should be a peak centered around $(m_b^2 + m_M^2 - m_q^2)/2m_b$ with a spread of a few hundred MeV. The energy of outgoing quark will be similar to that of the meson and become ~ 2 GeV numerically. The hadronization process of the quark will lead to low average multiplicity about 3/event. They insisted that the combinatorics problem in discriminating against background is not so difficult. They considered the tree $\times$ penguin and penguin $\times$ penguin type processes to estimate the partial rate asymmetries and to consider electroweak penguin dominated branching ratios.

In this letter, we suggest a new extraction method of γ using the semi-inclusive two-body decays of the type $b \rightarrow D^0(\bar{D}^0)s$ and $b \rightarrow D_{CP}s$ which come from only tree diagrams (see Fig. 1). These modes have the same advantage as other semi-inclusive decays given in Ref. [13]. The theoretical values of the decay rates would be less uncertain than the exclusive modes because the hadronic form factors are replaced with the calculation of quark diagrams. As these decay modes are semi-inclusive processes and final states involve a kind of isospin state, we also expect that they are free from the long distance effects of strong interaction. Because we consider decays of b -quark, all kinds of B hadrons can be used in this analysis.

The effective Hamiltonian relevant to $b \rightarrow Ds$ decays is given by

$$\mathcal{H}_{eff} = -\frac{G_F}{\sqrt{2}} [V_{cb}V_{us}^* \{c_1(\bar{s}u)_{V-A}(\bar{c}b)_{V-A} + c_2(\bar{c}u)_{V-A}(\bar{s}b)_{V-A}\} + V_{ub}V_{cs}^* \{c_1(\bar{s}c)_{V-A}(\bar{u}b)_{V-A} + c_2(\bar{u}c)_{V-A}(\bar{s}b)_{V-A}\} + h.c.], \quad (2)$$

where $c_{1(2)}$ are the Wilson coefficients and the subindex $V-A$ denotes $\gamma_\mu(1-\gamma_5)$ structure.

Let us introduce the relevant amplitudes as follows,

$$\begin{aligned} A(b \rightarrow D^0 s) &= A(\bar{b} \rightarrow \bar{D}^0 \bar{s}) = \mathcal{A}, \\ e^{i\gamma} A(b \rightarrow \bar{D}^0 s) &= e^{-i\gamma} A(\bar{b} \rightarrow D^0 \bar{s}) = \mathcal{A} R_b, \end{aligned} \quad (3)$$

where $R_b = \sqrt{\rho^2 + \eta^2} = 0.36 \pm 0.08$. The initial state $b(\bar{b})$ is isosiglet and the final states are isodoublet. Hence these processes are described by the effective Hamiltonian of $|\Delta I| = 1/2$ and all amplitudes are given by the a complex number $\mathcal{A}$ with same strong phases and different CKM factors. It is a main advantage of using these semi-inclusive decays that there is no relative strong phase in the above amplitudes.

The semi-inclusive decay rates into flavor specific states of D meson are given by

$$\begin{aligned} \Gamma(b \rightarrow D^0 s) &= \Gamma(\bar{b} \rightarrow \bar{D}^0 \bar{s}) = |\mathcal{A}|^2 F_{P.S.}, \\ \Gamma(b \rightarrow \bar{D}^0 s) &= \Gamma(\bar{b} \rightarrow D^0 \bar{s}) = |\mathcal{A}|^2 R_b^2 F_{P.S.}, \end{aligned} \quad (4)$$

where $F_{P.S.}$ is phase space factor and we neglect the small phase space differences.

On the other hand, using the definition of CP eigenstates of D mesons, $D_{1(2)} = \frac{1}{\sqrt{2}}(D^0 \pm \bar{D}^0)$, and neglecting the small $D^0 - \bar{D}^0$ mixing, we obtain the decay rates into CP eigenstate of final D meson:

$$\begin{aligned} \Gamma(b \rightarrow D_1 s) &= \Gamma(\bar{b} \rightarrow D_1 \bar{s}) = \frac{1}{2} |\mathcal{A}|^2 F_{P.S.} (1 + R_b^2 + 2R_b \cos \gamma), \\ \Gamma(b \rightarrow D_2 s) &= \Gamma(\bar{b} \rightarrow D_2 \bar{s}) = \frac{1}{2} |\mathcal{A}|^2 F_{P.S.} (1 + R_b^2 - 2R_b \cos \gamma). \end{aligned} \quad (5)$$

Decay rate ratios $\mathcal{A}_i$ between CP eigenstates and flavor specific states in the final D mesons are defined as follows,

$$\begin{aligned}\mathcal{A}_i &= \frac{\Gamma(b \rightarrow D_i s) + \Gamma(\bar{b} \rightarrow D_i \bar{s})}{\Gamma(b \rightarrow D_1 s) + \Gamma(\bar{b} \rightarrow D_1 \bar{s}) + \Gamma(b \rightarrow D_2 s) + \Gamma(\bar{b} \rightarrow D_2 \bar{s})} \\ &= \frac{\Gamma(b \rightarrow D_i s) + \Gamma(\bar{b} \rightarrow D_i \bar{s})}{\Gamma(b \rightarrow D^0 s) + \Gamma(\bar{b} \rightarrow \bar{D}^0 \bar{s}) + \Gamma(b \rightarrow \bar{D}^0 s) + \Gamma(\bar{b} \rightarrow D^0 \bar{s})},\end{aligned}\quad (6)$$

where $i = 1, 2$ is CP -even and odd eigenstates respectively and in the second line, we use the following relation coming from Eq. (4) and (5) :

$$\begin{aligned}&\Gamma(b \rightarrow D^0 s) + \Gamma(\bar{b} \rightarrow \bar{D}^0 \bar{s}) + \Gamma(b \rightarrow \bar{D}^0 s) + \Gamma(\bar{b} \rightarrow D^0 \bar{s}) \\ &= \Gamma(b \rightarrow D_1 s) + \Gamma(\bar{b} \rightarrow D_1 \bar{s}) + \Gamma(b \rightarrow D_2 s) + \Gamma(\bar{b} \rightarrow D_2 \bar{s}).\end{aligned}\quad (7)$$

Using Eq.(4), we can simplify the ratio $\mathcal{A}_i$ as follows,

$$\mathcal{A}_i = \frac{1}{2} \pm \frac{R_b}{1 + R_b^2} \cos \gamma, \quad (8)$$

where $\pm$ correspond to $i = 1, 2$ respectively. Note that these simple relations come from the fact that there is no relative strong phase between $A(b \rightarrow D^0 s)$ and $A(b \rightarrow \bar{D}^0 s)$ in Eq. (3).

We can also define a combined asymmetry $\mathcal{R}$ between CP -even and odd states as follows,

$$\begin{aligned}\mathcal{R} &= \mathcal{A}_1 - \mathcal{A}_2 \\ &= \frac{\{\Gamma(b \rightarrow D_1 s) + \Gamma(\bar{b} \rightarrow D_1 \bar{s})\} - \{\Gamma(b \rightarrow D_2 s) + \Gamma(\bar{b} \rightarrow D_2 \bar{s})\}}{\{\Gamma(b \rightarrow D_1 s) + \Gamma(\bar{b} \rightarrow D_1 \bar{s})\} + \{\Gamma(b \rightarrow D_2 s) + \Gamma(\bar{b} \rightarrow D_2 \bar{s})\}},\end{aligned}\quad (9)$$

Using Eq.(5) or Eq(8), $\cos \gamma$ is related to the asymmetry $\mathcal{R}$ as

$$\cos \gamma = \frac{\mathcal{R}(1 + R_b^2)}{2R_b}. \quad (10)$$

The sum of initial b and $\bar{b}$ states is used in the definition of the ratio $\mathcal{A}_i$ in Eq. (6) and the asymmetry $\mathcal{R}$ in Eq. (9). Hence there is no need tagging of the initial b and $\bar{b}$ states and it is an experimental advantage of this method.

From Eq. (8), (10) and using the present experimental value of $R_b = 0.36 \pm 0.08$, we can obtain the bound of the ratios $\mathcal{A}_i$ and the asymmetry $\mathcal{R}$:

$$\begin{aligned}0.18 &\leq \mathcal{A}_i \leq 0.82, \\ -0.64 &\leq \mathcal{R} \leq 0.64.\end{aligned}\quad (11)$$

If the ratios $\mathcal{A}_i$ and $\mathcal{R}$ are determined between the above range in the future experiments, we can constrain the angle γ using the experimental data.

Let's probe the feasibility of this method in determining the angle γ . We need to know the branching ratio of each mode and the detection efficiencies. In order to estimate the branching ratio of the relevant decay, we use the factorization approximation and obtain the relevant transition amplitudes :

$$\begin{aligned}
A(b \rightarrow D^0 s) &= \frac{G_F}{\sqrt{2}} V_{cb} V_{us}^* a_2 < D^0 | \bar{c} u_- | 0 > < s | \bar{s} b_- | b >, \\
A(b \rightarrow \bar{D}^0 s) &= \frac{G_F}{\sqrt{2}} V_{ub} V_{cs}^* a_2 < \bar{D}^0 | \bar{u} c_- | 0 > < s | \bar{s} b_- | b >,
\end{aligned} \tag{12}$$

where $a_2 = c_2 + c_1/N_c$ and $\bar{q}q'_- = \bar{q}\gamma_\mu(1 - \gamma_5)q'$.

The branching ratio is given by

$$\begin{aligned}
Br(b \rightarrow D^0 s) &= \left| \frac{V_{cb} V_{us}^*}{V_{ub} V_{cs}^*} \right|^2 Br(b \rightarrow \bar{D}^0 s) \\
&= \frac{G_F^2}{8\pi m_b} |V_{cb} V_{us}^*|^2 a_2^2 f_D^2 R \tau_b [2(p_s \cdot p_D)(p_b \cdot p_D) - (p_s \cdot p_b)m_D^2] \\
&\simeq 0.67 \times 10^{-4},
\end{aligned} \tag{13}$$

where $R = (1 + R_1^2 + R_2^2 - 2R_1 R_2 - 2R_1 - 2R_2)^{1/2}$ with $R_1 = (m_s/m_b)^2$ and $R_2 = (m_D/m_b)^2$. In this numerical calculation, we use the following parameter set : $\tau_b = 1.55 \times 10^{-12}\text{sec}$, $a_2 = 0.21$, $f_D = 200 \text{ MeV}$, $m_s = 120 \text{ MeV}$, $m_D = 1.87 \text{ GeV}$ and $m_b = 4.8 \text{ GeV}$. The values of the branching ratios depend on the specific parameter set, the factorization assumption and the Fermi motion of the b -quark in the B mesons. However the above typical values are enough to estimate the errors in determining the γ .

In order to estimate the uncertainty in the determination of the angle γ , we assume $3 \times 10^8 B\bar{B}$ events in B factories using e^+e^- annihilation at the $\Upsilon(4S)$ resonance. Tagging of $D^0(\bar{D}^0)$ is used $D^0 \rightarrow K^-\pi^+$, $D^0 \rightarrow K^-\pi^+\pi^+\pi^-$ and $D^0 \rightarrow K^-\pi^+\pi^0$ modes and its total efficiency is about 0.25. The CP even-state D_1 is identified by $D_1 \rightarrow \pi^+\pi^-$, K^+K^- and the observation rate is 5×10^{-2} which is quoted in Ref. [5]. The tagging of CP odd state D_2 uses the $D_2 \rightarrow K_s\pi^+\pi^-$ whose branching ratio is 5.4%. The observation rate is 3.6% as K_S is identified by $K_S \rightarrow \pi^+\pi^-$ mode whose branching fraction is about 2/3.

The number of the observable events can be obtained by the product of the number of the $B\bar{B}$ event, the branching ratio of the each modes and the detection efficiencies of the final particles. The statistical error in the branching ratio is approximately given by $\Delta Br/Br \approx 1/\sqrt{N_{\text{obs}}}$. The numerical values of the statistical error become about 1.4% and 3.9% for $b(\bar{b}) \rightarrow D^0 s(\bar{D}^0 \bar{s})$ and $b(\bar{b}) \rightarrow \bar{D}^0 s(D^0 \bar{s})$, respectively. For the modes with CP eigen states in the final states, the values depend on the angle γ . Presenting the values in order of $b \rightarrow D_1 s(\bar{b} \rightarrow D_1 \bar{s})$ and $b \rightarrow D_2 s(\bar{b} \rightarrow D_2 \bar{s})$, they become 3.4%(4.0%) and 6.3%(7.4%) for $\gamma = 30^\circ$, 4.0%(4.7%) and 4.4%(5.2%) for $\gamma = 80^\circ$ and 5.9%(6.9%) and 3.4%(4.0%) for $\gamma = 140^\circ$, respectively.

Using this information, we can estimate the error in determining γ . The result is given in Fig. 2, where the horizontal and vertical axis represent γ and $\Delta\gamma$ in degrees, respectively. The real line and dashed line present the error in γ determined using the ratio $\mathcal{A}_1$ and $\mathcal{A}_2$. The dotted line is error plot using the combined asymmetry $\mathcal{R}$. They all give the similar results. From 40° to 160° , we can determine γ with 4- σ accuracy. We also investigate the possibility to extract the information of the angle γ in the smaller number of $B\bar{B}$ events, 3×10^7 . The result is given in Fig. 3. Even in this case, our method may give the reliable results that the angle can be determined with 2- σ accuracy for $40^\circ \lesssim \gamma \lesssim 60^\circ$ and 3- σ accuracy for $60^\circ \lesssim \gamma \lesssim 160^\circ$.

In conclusion, we proposed a new extraction method of γ using the semi-inclusive decays of the type $b \rightarrow Ds, \bar{D}s, D_{CPs}$. These decays are relevant to only tree diagram (Fig. 1) and there is no relative strong phase depending on the final states because the final states are related to the semi-inclusive modes and only one kind of isospin state. Then we can simply relate $\cos \gamma$ to the R_b and the ratios $\mathcal{A}_i, \mathcal{R}$ which should be determined in future experiment. Since we consider decays of b -quark, all kinds of b -hadrons can be used in this analysis. We also probe the feasibility of the suggested method in this paper by estimating the statistical errors in determination of the angle γ which is given in Fig. 2. The value of γ should be determined with $4\text{-}\sigma$ accuracy for $40^\circ \lesssim \gamma \lesssim 160^\circ$ using $3 \times 10^8 B\bar{B}$ events in our method.
